

Valuation and hedging of cryptocurrency inverse options

V. Lucic* A. Sepp[†]

Published in Quantitative Finance¹

Abstract

Currently the most liquidly traded options on the crypto underlying are the so-called inverse options. An inverse option contract is quoted and traded in the units of the underlying cryptocurrency. The main economic reason for popularity of inverse contracts in the crypto exchanges (such as Deribit) is that inverse contracts enable to operate without maintaining fiat cash accounts. For the theoretical part, we show that inverse options are just regular vanilla options considered under the martingale measure using the underlying as the numéraire. This measure requires an adjustment to option delta. For the empirical part, we use Deribit options data of past four years to backtest various delta-hedged option strategies. We introduce USD and Coin accounting of trading P&L which is important for designing strategies in crypto options. We show empirically that USD and Coin accounting rules are equivalent when performance is measured in Coin and USD units, respectively. We establish that the risk-premia observed in options on Deribit is negative and significant so that strategies selling volatility are expected to generate positive risk-adjusted performance in the long-term.

Keywords: Inverse options, Deribit options, Change of numéraire, Cryptocurrencies

1 Introduction

Options on digital assets have developed significantly over the recent years, both on the classical exchanges (CME) but also within the DeFi space, specific to the digital assets only. Amongst the centralised exchanges (CEX) hosting options on digital assets, Deribit has majority of the market share, covering 86% of the open interest as of August 2023. One of specific features of trading options on Deribit is that the exchange does not deal with fiat currencies, so that the price and the hedge ratio of the options are expressed in the digital currencies (BTC, ETH) rather than the usual “payout currency”

(in this case USD). In this work, extending the earlier note [Lucic \[2021\]](#), we show how this change naturally fits into the well-established no-arbitrage framework utilizing numéraire invariance, developed some thirty years ago.

Further, we provide examples of backtests of option trading strategies, putting this theory in action. For a proper design of option strategies dealing with inverse options, We introduce the USD and Coin-based accounting rules for P&L of systematic option strategies. We show that, if an investor wants to keep a long bias to cryptocurrencies, she must follow Coin-based accounting. On the other hand, USD-based accounting produces market-neutral exposure over the long-time. Importantly, the risk-adjusted performances of USD and BTC-based accounting rules are equal when measured in USD and Coin, respectively. For an example, 15% per annum (p.a.) return for both USD and Coin performances implies that USD and Coin accounts increased by 15% being market neutral to BTC. However, the USD value of the Coin account and as well as the Coin value of USD account will be impacted by the change of BTC during the reporting period. These specifics are important for implementing and reporting of trading strategies in inverse options.

Using Deribit options data for the past four years, we apply the backtest simulation of systematic roll-based strategies selling and buying option with dynamic delta-hedging. We show that options feature negative risk-premia (higher for BTC and lower for ETH) indicating that buying and delta-hedging put and call options produces negative returns in the long run².

1.1 Literature review

In a related study, [Alexander et al. \[2023\]](#) consider the valuation of crypto inverse options in the Black-Scholes model using FX setup in [Garman and Kohlhagen \[1983\]](#). As for the empirical part, [Alexander and Imeraj \[2023\]](#) analyze hedging of Bitcoin inverse options using data from Deribit exchange and utilizing a few of skew-related adjustment for Black-Scholes delta. In a similar empirical study, [Matic et al. \[2023\]](#) apply various stochastic volatility and jump models to test the effectiveness of hedging Bitcoin options. In both studies, it is not clear if authors use the premium adjustment for inverse options (which comes directly out of the numéraire change).

In recent years several working papers appeared presenting incorrect formulas for prices and deltas for inverse options, creating some confusion among practitioners. Our paper provides with a thorough derivations and analysis of valuation and delta-hedging of inverse options under a generic model and with an intuition behind using the Black-Scholes model for hedging inverse options. Our inputs are important because inverse options play a vital role in crypto ecosystem³.

²The academic literature defines the volatility risk premia as the spread between realised and implied volatilities, while practitioners define the risk-premia the other way around as the spread between implied and realised volatilities. We stick with the academic definition of the volatility risk-premia, which implies that the observed risk-premia in cryptocurrencies is negative so that performance of strategies buying options is expected to negative. In this content, what practitioners' definition of volatility risk-premia refers to strategies selling options so practitioners' risk-premia is positive.

³Deribit exchange and a few providers of crypto data analytics use Blacks futures model for marking and risk metrics of inverse options.

2 Arbitrage-based Valuation

We provide a general approach for valuation and hedging of inverse options using martingale-based valuation and the numéraire invariance.

2.1 Securities

We denote the price of the underlying cryptocurrency at time T by S_T , and we assume that the price is quoted in USD. The option underlying could be either the spot or the futures contract. We consider “regular” call and puts payoffs settled in USD cash at maturity time T , respectively, as follows

$$u^{\text{call}}(S_T) = \max \{S_T - K, 0\}, \quad u^{\text{put}}(S_T) = \max \{K - S_T, 0\}. \quad (1)$$

The payoffs of “inverse” call and put options are converted to units of the underlying asset at maturity T as follows

$$r^{\text{call}}(S_T) = \frac{1}{S_T} \max \{S_T - K, 0\}, \quad r^{\text{put}}(S_T) = \frac{1}{S_T} \max \{K - S_T, 0\}. \quad (2)$$

Finally we consider the “regular” forward and futures contracts with payoff given by

$$u^{\text{futures}}(S_T) = S_T - K, \quad (3)$$

where K is the USD strike price (typically $K = S_0$). The corresponding “inverse” futures contract has the following payoff

$$r^{\text{futures}}(S_T) = \frac{1}{S_T} (S_T - K). \quad (4)$$

Deribit supports only (perpetual and termed) futures with inverse payoffs. Some crypto exchanges support both types with most liquidity available for inverse futures.

2.2 Martingale Valuation

We consider a continuous-time market with a fixed horizon date $T^* > 0$ defined on a filtered probability space $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}, \mathbb{P})$. We consider the price process S_t adapted to $\{\mathcal{F}_t\}$ which models prices of cryptocurrencies. When dealing with incomplete markets, e.g. dynamics including stochastic volatility or jumps, we fix a martingale measure using specific risk preferences (see for an example [Lewis \[2000\]](#)).

We introduce a risk-free rate⁴ $r(t)$ with the value of one units of the money market account (MMA) $M(T)$ given by

$$M(T) = e^{\int_0^T r(s) ds}. \quad (5)$$

We introduce an equivalent martingale measure $\mathbb{Q}$ corresponding to the numéraire M . Given payoff function $u(S_T)$ at time T , we denote the time- t value of an option yielding

⁴Most DEX-es and CEX-es (such as Deribit) assume zero discount rate when marking their listed options. We would call r as a low risk opportunity cost available in DeFi with the risk being a potential hack of blockchain technology when deposited and staked assets could be appropriated. Staking of high quality stablecoins in top DeFi protocols would yield 1% – 2% in the current environment, which is far less than rates on government short-term bonds in traditional markets (4% – 5% as of October 2023).

this payoff by $V(t, S, \cdot)$, where $\cdot$ stands for additional state variables (for an example, stochastic volatility). By martingale valuation we obtain

$$V(t, S, \cdot) = M(t) \mathbb{E} \left[\frac{1}{M(T)} u(S_T) | \mathcal{F}_t \right], \quad (6)$$

with expectation $\mathbb{E}$ taken under the MMA measure $\mathbb{Q}$. Under the measure $\mathbb{Q}$ the forward price is given by

$$\mathbb{E}[S_T | \mathcal{F}_t] = S_t e^{\int_0^T (r(s) - q(s)) ds}, \quad (7)$$

where we assume deterministic interest rate $r(t)$ and $q(t)$ is deterministic borrow rate⁵.

Next, we define the inverse martingale measure $\tilde{\mathbb{Q}}$ as the one corresponding to S as numéraire. The option value function, denoted by $\tilde{V}(t, S)$, with the payoff paid in units of S , equals to

$$\tilde{V}(t, S, \cdot) = \tilde{\mathbb{E}} \left[\frac{1}{S_T} u(S_T) | \mathcal{F}_t \right], \quad (8)$$

with expectation $\tilde{\mathbb{E}}$ taken under the inverse martingale measure $\tilde{\mathbb{Q}}$.

For the future reference we state the change of numéraire theorem (e.g. Theorem 1 in [Geman et al. \[1995\]](#)) applied to this setting.

Theorem 1. *Assume a complete market and that both the MMA measure $\mathbb{Q}$ and the inverse measure $\tilde{\mathbb{Q}}$ are equivalent martingale measures. Then the values of options under the MMA measure in Eq (6) and under the inverse measure are in Eq (8) satisfy*

$$M(t) \mathbb{E} \left[\frac{1}{M(T)} u(S_T) | \mathcal{F}_t \right] = S_t \tilde{\mathbb{E}} \left[\frac{1}{S_T} u(S_T) | \mathcal{F}_t \right]. \quad (9)$$

We call the MMA measure as USD measure and the inverse measure as BTC measure. Theorem (1) establishes the no-arbitrage equality between the value $V(t, S, \cdot)$ of regular European option under the USD measure and the value $\tilde{V}(t, S, \cdot)$ of inverse option under the BTC measure given as follows

$$V(t, S, \cdot) = S_t \tilde{V}(t, S, \cdot) \quad (10)$$

where $\cdot$ includes state variables in addition to S . Thus given a quoted price (on Deribit exchange) of inverse option, we obtain the price of the regular option by multiplying by the underlying price.

The assumption of the existence of the USD and BTC measures in Theorem (1) is readily established under the log-normal Black-Scholes dynamics because these dynamics are strict martingales under both MMA and inverse measures. To apply models with stochastic volatility (SV), we may need to impose certain restrictions on model parameters. For an example, exp-OU SV model is not arbitrage-free when the asset-volatility correlation is positive (see [Sepp and Rakhmonov \[2023\]](#) for details and for valuation of inverse options under a log-normal stochastic volatility model).

⁵For a CEX, the borrow rate q is the negative of the funding rate reported by the CEX (by the convention of crypto CEX-es, the funding rate is the rate paid by traders with long positions). For a DeFi protocol, the borrow rate q is the accrued borrow rate.

Corollary 1 (Delta hedge of inverse options). *Differentiating Eq (10) with respect to S , we obtain the hedge ratio for the inverse options*

$$\partial_S \tilde{V}(t, S, \cdot) = \frac{1}{S} \left[\partial_S V(t, S, \cdot) - \tilde{V}(t, S, \cdot) \right] \quad (11)$$

Thus, the delta-hedge of the inverse option must be implemented using an inverse perpetual or a termed futures contract with payoff in Eq (4) with the units of this inverse contract computed by

$$\tilde{\Delta}(t, S, \cdot) = \Delta(t, S, \cdot) - \frac{V(t, S, \cdot)}{S} \quad (12)$$

where $\Delta(t, S, \cdot)$ is the delta hedge (number of units in the underlying asset or regular futures) of the regular option.

This is a model-independent result (for a complete market), which allows to compute the model delta for inverse options using model price and delta for regular options. In Section 3.1 we link the delta adjustment in Eq (12) to numéraire invariance, while in Section 3.2, we link it to the decomposition of option’s profit-and-loss.

We note that options on Deribit exchange are option on the futures. Theorem (1) applies using S_t are the price of the future underlying the option. Then option delta $\tilde{\Delta}(t, S)$ in Eq (12) specifies the number of contracts on the underlying inverse future for the delta-hedging.

3 Hedging

The hedging ratios for the inverse options can be obtained directly from the replicating portfolio for the “regular option” using using Eq (12). By the numéraire invariance participle, a self financing portfolio remains self-financing after expressing its units in terms of different tradeable assets.

3.1 Black-Scholes model

We provide an alternative derivation of delta in Eq (12) and intuition behind it for [Black and Scholes \[1973\]](#) model. The USD-denominated replicating portfolio is given by

$$V_t^{USD} = S_t N(d_1(t)) - K N(d_2(t)), \quad (13)$$

consisting of long $N(d_1(t))$ units of regular BTC futures contract and short $KN(d_2(t))$ units of USD-cash. Thus, the BTC-denominated replicating portfolio is

$$V_t^{BTC} = N(d_1(t)) - R_t K N(d_2(t)), \quad (14)$$

consisting of long $N(d_1(t))$ units of BTC cash and short $KN(d_2(t))$ units of the inverse futures contract R_t . Using Eq (13), this gives the R_t -Delta of the BTC-denominated contract as

$$-KN(d_2(t)) \equiv V_t^{USD} - N(d_1(t))S_t. \quad (15)$$

The incremental P&L of the Delta hedge is therefore given by

$$(R_{t+\delta t} - R_t) (V_t^{USD} - N(d_1(t))S_t) = \frac{S_{t+\delta t} - S_t}{S_{t+\delta t}} \left(N(d_1(t)) - \frac{V_t^{USD}}{S_t} \right), \quad (16)$$

so when implementing BTC-denominated Delta-hedging using (USD-denominated) BTC futures, the required number of units of the inverse futures is given by

$$\Delta_t^{BTC} = \Delta_t^{USD} - \frac{V_t^{USD}}{S_t}. \quad (17)$$

This essentially the “percentage spot Delta” used in FX options pricing (see, e.g. Section 3.2.2 of Clark [2011]). It also easily follows that the above argument can be applied to any one-factor model (e.g. local volatility), providing an alternative derivation of (12).

3.2 P&L explain

The standard P&L explain provides an intuition behind the delta adjustment. We consider Black mark of option premium $V^{USD}(t; T)$:

$$V_t^{BTC} = \frac{V_t^{USD}}{S_t}. \quad (18)$$

The P&L explain for time increment Δt is obtained as

$$\begin{aligned} \text{P\&L}_{t+\delta t}^{BTC} &= \frac{V_{t+\delta t}^{USD}}{S_{t+\delta t}} - \frac{V_t^{USD}}{S_t} \\ &= \frac{\Theta_t^{USD} \delta t + \frac{1}{2} (S_{t+\delta t} - S_t)^2 \Gamma_t^{USD}}{S_{t+\delta t}} + \frac{S_{t+\delta t} - S_t}{S_{t+\delta t}} \left(\Delta_t^{USD} - \frac{V_t^{USD}}{S_t} \right), \end{aligned} \quad (19)$$

where in the second line we use expansion in Taylor series into theta Θ_t^{USD} , gamma Γ_t^{USD} , and delta Δ_t^{USD} terms. The first term in the second line is the classic theta/gamma P&L, and the second order is the premium adjusted delta. The delta hedge must be implemented using an inverse future, which neutralizes the delta exposure.

4 P&L of Inverse Perpetual Futures

The perpetual futures is a core delta-one product on cryptocurrency exchanges, including the Deribit exchange, because, like a traditional futures, the perpetual (perp in short) futures can be traded on margin with flexible leverage. The perpetual futures does not have an expiration date. The carry of the perpetual future is determined by the so-called funding rate, which is designed to keep the price of the futures contract F_t close to the spot price S_t .

The underlying asset of option contract is the termed futures contract with the same settlement as option maturity. However, the future market is much less liquid than the market of perpetual futures. Here we consider in depth the utilization of perpetual future for delta hedging of cryptocurrency options using Deribit exchange as the key example.

4.1 Deribit Conventions

We consider the method applied by Deribit exchange to compute the mark price of the perpetual future. We then apply this method for P&L computations in both live and historical simulations. The Deribit exchange computes the three market quantities as follows ⁶.

⁶See <https://www.deribit.com/kb/deribit-inverse-perpetual> for details.

1. S_t is the spot price (the so-called Deribit index price), which is computed by Deribit and which tracks a basket of cryptocurrency spot prices across other major crypto centralised exchanges.
2. FP_t is the fair price of the perpetual futures computed as the average of fair impact ask and bid prices as

$$FP_t = \frac{1}{2} (FairImpactBid_t + FairImpactAsk_t) \quad (20)$$

where Fair Impact Bid and Ask Prices are average prices at which 100,000 USD worth of contracts can be bought and sold, respectively (which are computed from the current order book).

3. F_t is the mark price of the perpetual futures computed by

$$F_t = S_t + EMA(FP_t - S_t) \quad (21)$$

where EMA is 30 second exponential moving average.

Once these quantities are computed, the funding rate f_t on Deribit is computed by:

$$f_t = \max \{0.025\%, PremiumRate_t\} + \min \{-0.025\%, PremiumRate_t\} \quad (22)$$

where $PremiumRate$ is computed by:

$$PremiumRate_t = \frac{F_t - S_t}{S_t} \quad (23)$$

If the price of perp future F_t trades at a premium to the index price S_t (indicating there is a buying pressure) higher than 0.025%, long holders of the contract pay the funding rate t_t to short holders, and vice verse.

Deribit accrues funding fees continuously through the day based on the position exposures using the prevailing funding rate updated every second. Account's equity (in BTC and ETH) is credited/debited with accrued funding rate and P&L daily at 8.00 AM.

When we open an inverse futures contract, the notional exposure in USD N^{USD} is fixed at the time of trade and it stays constant during the lifetime of the trade. At the same time, BTC exposure to the perpetual futures is floating as N^{USD}/F_t . In opposite, for a linear futures contract, the number of BTC units is fixed through the lifetime of the trade, while USD exposure is floating.

The P&L in BTC for an inverse futures contract with notional N^{USD} over period δt is computed by:

$$P\&L^{BTC}(t + \delta t) = N^{USD} \left(\frac{1}{F_t} - \frac{1}{F_{t+\delta t}} \right) \quad (24)$$

where F_t is the mark price of the perpetual future quoted by Deribit and computed by Eq (21). The corresponding P&L in USD is given by

$$P\&L^{USD}(t + \delta t) = N^{USD} \left(\frac{1}{F_t} - \frac{1}{F_{t+\delta t}} \right) S_{t+\delta t}. \quad (25)$$

The interpretation of Eq (25) is that BTC P&L in Eq (24) is evaluated using the mark price, which is closed to a liquidation price of the position in the perp futures for a

relatively small position, while the P&L in USD computed at the prevalent spot rate. As a result, when the position is closed at time $t + \delta t$, the P&L in BTC is determined using mark price $F_{t+\delta t}$ and the P&L in USD is determined by swapping BTC P&L into USD using the index price $S_{t+\delta t}$ ⁷.

The cumulative delta-hedge P&L is computed by:

$$\begin{aligned} \text{Roll P\&L}^{BTC} &= \sum_t N_t^{USD} \left(\frac{1}{F_t} - \frac{1}{F_{t+\delta}} \right) = \sum_t \Delta_t^{BTC} F_t \left(\frac{1}{F_t} - \frac{1}{F_{t+\delta}} \right) \\ &= \sum_t \Delta_t^{BTC} \left(\frac{F_{t+\delta} - F_t}{F_{t+\delta}} \right) \end{aligned} \quad (26)$$

where Δ_t^{BTC} is the (BTC) value of the instruments held in the delta hedge at time t .

The corresponding USD-based Roll P&L is computed using Eq (26) as follows

$$\text{Roll P\&L}^{USD} = \sum_t \Delta_t^{BTC} \left(\frac{F_{t+\delta} - F_t}{F_{t+\delta}} \right) S_t \quad (27)$$

The interpretation is time- t_h P&L in BTC is swapped to USD using the spot BTC-USD rate S_t .

It is clear that Roll P&L^{BTC} evaluated as the current BTC-USD rate is different from Roll P&L^{USD}:

$$\text{Roll P\&L}^{BTC} \neq \frac{1}{S_t} \text{Roll P\&L}^{USD} \quad (28)$$

4.2 Delta-hedge Implementation

As we noted, the underlying of options on Deribit exchange are termed futures contracts with the same settlement date as the option expiry date. Thus, prices of termed futures are used for computing deltas and settlement prices of listed options. However, termed futures are less liquid than the perpetual future. Moreover for some maturities (typically new maturities of front two weeks), futures are not traded, with Deribit exchange using a linear interpolation for quoting. As a result, for delta-hedging of options, we convert delta exposures to termed futures into the exposure to the perpetual futures, in order to reduce transaction costs for delta-hedging purposes.

We compute aggregated delta Δ_{perp}^{BTC} of the portfolio of K options for delta-hedging using the inverse perp future as follows

$$\Delta_{perp}^{BTC}(t, T) = -\frac{1}{F_t} \left(\sum_{k'} F_{k'}(t, T) M_{k'} \Delta_{k'}^{BTC}(t, T) \right), \quad (29)$$

where $\Delta_k^{BTC}(t, T)$ is options delta with respect to the futures contract as marked by Deribit⁸, M_k is the position size, $F_k(t, T)$ and F_t are the marked prices of the termed future and the perpetual inverse future, respectively.

⁷The Deribit exchange supports trading in the spot (although it is much less liquid compared to perps market), so this approach is viable for converting P&L to USD-based accounts. Otherwise BTC P&L can be transferred to other wallets and exchanges to spot prices in other trading venues.

⁸For each quoted option Deribit exchange is using Eq (17) for premium adjusted delta. Deribit has a proprietary model to fit implied Black-Scholes volatilities from bid-ask prices of inverse options (using Eq (10) to convert their prices to prices of regular options) and to compute respective Blacks deltas. We do not apply any skew adjustment to the quoted delta and leave this analysis for future research.

The spot price of the perpetual inverse future is very close to the current spot price, with any difference (in perp premium) being charged as the funding cost. The cost of funding a position in perpetual future is determined using a continuously updated funding rate for the holding period of 8 hours⁹. We use the funding rate on hourly basis, $f(t_q)$ to compute the realised costs from t_0 to T as follows

$$DeltaFunding^{BTC}(t; t_0, T) = -\frac{1}{8} \sum_{t_q \in (t_0, t]} f(t_q) \Delta_{perp}^{BTC}(t_q, T), \quad (30)$$

here $f(t_q)$ is reported Deribit funding rate (which is applied for the time period of 8 hours) normalized by the factor of 8, t_q is hour timestamps during period $(t_0, T]$, $\Delta_{perp}^{BTC}(t_q)$ is portfolio delta computed using (29). The corresponding USD value of delta funding is

$$DeltaFunding^{USD}(t; t_0, T) = -\frac{1}{8} \sum_{t_q \in (t_0, t]} S_{t_q} f(t_q) \Delta_{perp}^{BTC}(t_q, T). \quad (31)$$

where we use the spot price S_t to compute the accrued funding in BTC to USD at the prevailing spot exchange rate S_t .

The minus sign in Eqs (30) and (31) reflects the convention of Deribit (and of all other crypto exchanges) that a long positions pays the funding rate and, in opposite, a short position receives the funding rate.

In top subplots of Figure (1), we show the funding rates for BTC and ETH perpetual future as reported by Deribit. We see that BTC and ETH funding rates are positive on average, they tend to spike on the positive side during bull regimes (increased number of long positions need to pay to a smaller number of short positions). In the bottom subplot, we show the cumulative funding costs on holding long one perpetual futures contract, and costs on holding a dynamic position for delta-hedging of long and short ATM call option (for brevity the position size is one BTC or ETH for each roll implemented weekly). A delta-hedged position in short ATM call is long delta, so that the accrued funding costs are negative in the long term for this position. In opposite, a delta-hedged strategy selling ATM call option is short delta so that the strategy realises positive funding costs in the long term.

⁹See specification of the funding rate here <https://www.deribit.com/kb/deribit-inverse-perpetual>.

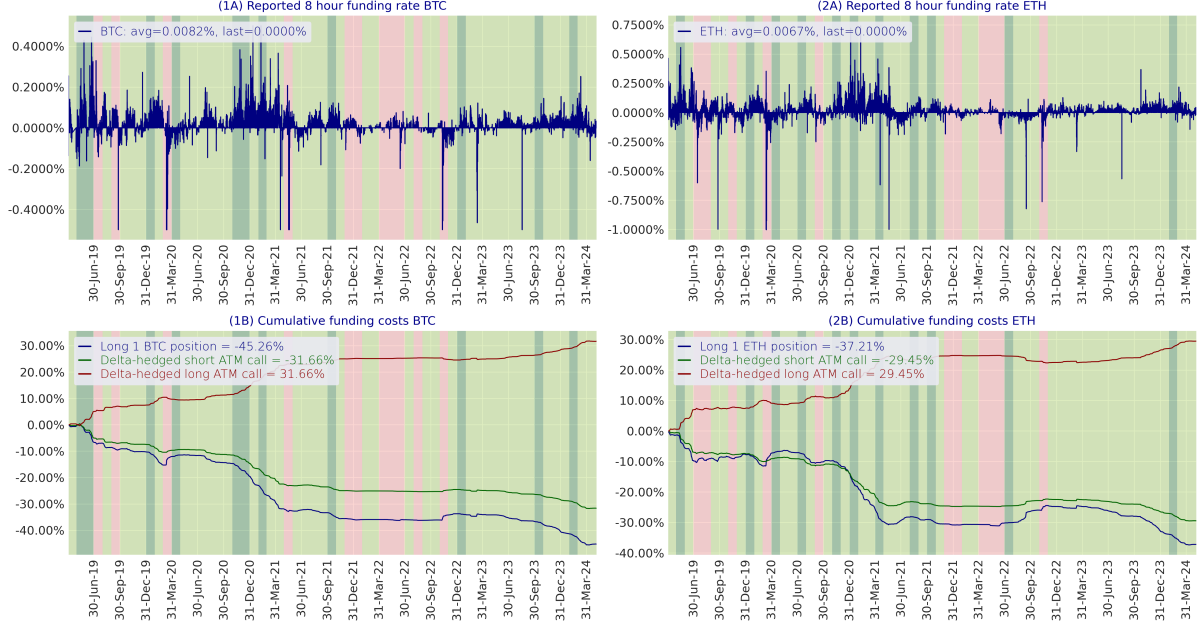

Figure 1: (A) 8 hour funding rate reported by Deribit, (B) realised cumulative funding costs for long one coin, and delta-hedged short ATM and long ATM calls. The background color is obtained by ordering the monthly returns from lowest to highest and the splitting the 16% of worst returns into the "bear" regime (pink color), 16% of best returns into the bull regime (dark green color), and remaining regimes into "normal" regimes (light green color).

From Figure (1), we see that the funding costs accrued for a delta-hedged position can be substantial (delta-hedged strategy selling ATM calls accrues -25% total costs over three year period or -8% per annum on average). Thus, funding costs must be taken into account for historical simulation of option strategies. We note that the implementation of hedging delta Δ_{perp}^{BTC} in Eq (29) exposes a trader to the basis risk when the carry of a term future contract varies from realized funding costs of the perpetual future contract. Typically the funding rate and the carry of the front and monthly futures are highly correlated, so the basis risk is not significant. Moreover, this basis risk is compensated by lower costs of trading in the perpetual future. We note that Deribit exchange allows for spot trading too, but the spot market is illiquid.

5 Backtesting option strategies using Deribit data

We consider essential steps for the design and implementation of systematic strategies trading in inverse crypto options. For simulations of systematic option strategies and empirical results, we use Deribit data of all traded options contracts on Bitcoin (BTC) and Ether (ETH) with hourly frequency from 31 March 2019 to 18 September 2023. Our approach is generic for all coin margined trading venues. We use the term Coin as notation for either BTC or ETH underlying. For clarity, we use notation such as Π_0^{BTC} to denote Coin-measured variables.

5.1 P&L accounting for option strategies

Deribit exchange settles margin requirements and realised trading P&L in Coin so the coin-based accounting is natural when dealing with inverse options. As an alternative, we will consider USD-based accounting with Coin P&L at time t exchanged into USD using

BTC-USD (or ETH-USD) spot exchange rate at time t . We show that these accounting rules result in different terminal outcomes and risk profiles, so that, portfolio managers and investors must understand the difference.

We introduce the following accounting methods.

1. USD-based accounting with the initial deposit/margin funded with USD and with Coin (BTC or ETH) P&L instantly exchanged to USD.
2. Coin-based accounting with the initial deposit/margin funded with BTC or ETH and with P&L reporting in same Coin.

For trading in BTC and ETH options at Deribit exchange, a trader needs to fund BTC or ETH, respectively. Thus, USD-based accounting requires depositing Coin collateral and hedging it using perpetual futures and instant swapping of the coin-based P&L into USD. Coin-based accounting is natural for investors who desire to keep the exposure and P&L to BTC or ETH.

We note that funded USD account could earn interest income. For simplicity, we skip the interest rate from the analysis. The convention of Deribit exchange is to use zero USD and BTC rates for computing mark prices and deltas. In line, we report Sharpe ratios of simulated strategies assuming that the interest rate is zero.

5.1.1 Funded strategies selling options without delta-hedging

We examine some popular strategies in Decentralised Finance (DeFi) which regularly sell options without delta-hedging such as covered call (the strategy is long either BTC or ETH coin and sells at-the-money calls covered by held coins) and put selling (the strategy holds the collateral and sells at-the-money puts against the collateral). Each strategy represents a sequence of non-overlapping rolls (such as weekly or monthly rolls) where options are sold at the inception of the n -th roll and these options are settled using the available collateral at the close of the roll.

Coin accounting

We assume that the strategy is funded with initial deposit of Π_0^{BTC} coins. The realized P&L in BTC of the n -th roll is given by

$$P\&L^{BTC}(t; t_0^n, T^n) = -N(t_0^n) (V^{BTC}(t, T^n) - V^{BTC}(t_0^n, T^n)), \quad (32)$$

where t_0^n is the roll inception time, T^n is the maturity time of option in the roll, and t is current time, $N(t_0^n)$ is the amount of BTC contracts sold at the roll inception. For 100% covered strategy, the number of sold contracts equals the amount of coins in the portfolio, $N(t_0^n) = \Pi^{BTC}(t_0^n)$.

We let $\{t_0^n\}$, $n = 1, 2, \dots$, denote times of the rolls. The cumulative P&L during time period $[t_0^1, t]$ of the strategy realised over n rolls is given by

$$CumP\&L^{BTC}(t) = \sum_{n'=1..n-1} P\&L^{BTC}(T^{n'}; t_0^{n'}, T^{n'}) + P\&L^{BTC}(t; t_0^n, T^n), \quad (33)$$

where the first term is the cumulative realized P&L of prior $n-1$ rolls and the second term is the mark-to-market P&L of the current roll. For realised P&L of the roll at the end time T^n is computed using the option payoff (settlement) value, $V^{BTC}(T^n, T^n)$, computed by option payoff given spot rate S_{T^n} .

The account value in BTC at time t is the sum of the initial BTC deposit Π_0 and the cumulative P&L

$$\Pi^{BTC}(t) = \Pi_0^{BTC} + CumP\&L^{BTC}(t). \quad (34)$$

The account value in USD is computed using the current BTC-USD rate S_t as follows

$$\Pi^{USD}(t) = S_t \Pi^{BTC}(t). \quad (35)$$

It is important that the initial coin deposit Π_0^{BTC} is a part of P&L attribution for coin funded strategies when valuing their performance in USD.

USD accounting

Under USD-based accounting, we assume that the initial deposit, denoted by D_0^{USD} , is made in USD and the coin P&L is hedged by swapping realised BTC P&L into USD. Eq (32) for P&L in USD is modified as follows

$$P\&L^{USD}(t; t_0^n, T^n) = -N(t_0^n) (S_t V^{BTC}(t, T^n) - S_{t_0^n} V^{BTC}(t_0^n, T^n)), \quad (36)$$

where the spot rate $S_{t_0^n}$ is applied to swap option premium at the roll inception and current rate S_t is applied to calculate USD value of the current premium.

The cumulative P&L during time period $[t_0^1, t]$ realised over n rolls is given by

$$CumP\&L^{USD}(t) = \sum_{n'=1..n-1} P\&L^{USD}(T^{n'}; t_0^{n'}, T^{n'}) + P\&L^{USD}(t; t_0^n, T^n), \quad (37)$$

where for the n -th roll we use the spot price observed at the expiry, S_{T^n} , to convert final payoffs to USD, and we use the spot price at the roll inception, $S_{t_0^n}$, to swap sold premiums to USD.

The account value in USD at time t is the sum of the initial USD deposit D_0^{USD} and the cumulative P&L in Eq (37)

$$\Pi^{USD}(t) = D_0^{USD} + CumTotalP\&L^{USD}(t), \quad (38)$$

where in line with our assumption we do not consider interest income on USD value of the account. The corresponding account value in measured in Coin is given by:

$$\Pi^{BTC}(t) = \frac{1}{S_t} \Pi^{USD}(t). \quad (39)$$

5.1.2 Margin-based strategies with delta-hedging

We now consider a generic option trading strategy with delta-hedging. At the inception of each roll, the strategy buys and sells a portfolio of options which are held to the close of the roll, which equals options maturity time. We assume that the strategy includes holding of a portfolio with k options (or option legs). The strategy portfolio is delta-hedged regularly through the roll period.

Coin accounting

We assume that the count is funded with the initial coin deposit Π_0^{BTC} . Option P&L of the n -th roll's portfolio is given similarly to Eq (32) by

$$OptionP\&L^{BTC}(t; t_0^n, T^n) = \sum_{k'} N_{k'}(t_0^n) (V_{k'}^{BTC}(t, T^n) - V_{k'}^{BTC}(t_0^n, T^n)), \quad (40)$$

where $N_k(t_0^n)$ is the number of contracts traded ($N_k(t_0^n) < 0$ if options are sold or $N_k(t_0^n) > 0$ if options are bought).

We use Eq (26) to compute the Delta-hedge P&L by

$$\begin{aligned} DeltaP\&L^{BTC}(t; t_0^n, T^n) = & \sum_{t_h} \frac{F_{t_h} - F_{t_{h-1}}}{F_{t_h}} \Delta_{perp}^{BTC}(t_{h-1}, T^n) \\ & - \eta \sum_{t_h} |\Delta_{perp}^{BTC}(t_h, T^n) - \Delta_{perp}^{BTC}(t_{h-1}, T^n)| \\ & + DeltaFunding^{BTC}(t; t_0^n, T^n), \end{aligned} \quad (41)$$

where t_h are delta re-balancing times with $t_h \in [t_0^n, T^n]$, $\Delta_{perp}^{BTC}(t, T)$ is the position delta in perpetual futures given in Eq (29), F_t is the mark price of the perpetual future. The second term is the delta re-balancing costs with η being the trading costs which we assume to be proportional to coin value traded (see assumption 5.1). The last term $DeltaFunding^{BTC}(t; t_0^n, T^n)$ is the delta funding costs defined in Eq (30).

The total P&L of the n -th roll is thus computed by

$$TotalP\&L^{BTC}(t; t_0^n, T^n) = OptionP\&L^{BTC}(t; t_0^n, T^n) + DeltaP\&L^{BTC}(t; t_0^n, T^n). \quad (42)$$

Cumulative P&Ls from option premiums and delta-hedging realised during time period $[t_0^1, t]$ with n rolls are given by

$$\begin{aligned} CumTotalOptionP\&L^{BTC}(t) = & \sum_{n'=1..n-1} OptionP\&L^{BTC}(T^{n'}; t_0^{n'}, T^{n'}) + OptionP\&L^{BTC}(t; t_0^n, T^n) \\ CumTotalDeltaP\&L^{BTC}(t) = & \sum_{n'=1..n-1} DeltaP\&L^{BTC}(T^{n'}; t_0^n, T^n) + DeltaP\&L^{BTC}(t; t_0^n, T^n), \end{aligned} \quad (43)$$

where first terms are realised P&Ls and second terms are P&Ls of the current roll. The cumulative total P&L of the strategy is given by

$$CumTotalP\&L^{BTC}(t) = CumTotalOptionP\&L^{BTC}(t) + CumTotalDeltaP\&L^{BTC}(t). \quad (44)$$

This decomposition is useful for P&L explain of an option strategy as we show in Subplot (B1) of Figure (4).

The account value in BTC at time t is the sum of the initial BTC deposit Π_0^{BTC} and the cumulative P&L

$$\Pi^{BTC}(t) = \Pi_0^{BTC} + CumTotalP\&L^{BTC}(t). \quad (45)$$

The account value in USD is

$$\Pi^{USD}(t) = S_0 \Pi_0^{BTC} + S_t CumTotalP\&L^{BTC}(t), \quad (46)$$

where S_0 is the value of BTC at the time of initial deposit. It is important that we exclude P&L realised from a change in USD value of the initial deposit so that we use the spot rate S_0 . Thus, the value of the margin account reflects only the realized P&L in Eq (44) accrued through trading.

USD accounting

We assume that the strategy is funded using the initial USD deposit D_0^{USD} and the coin P&L (which is the native accounting of Deribit exchange) is hedged by swapping realised BTC P&L into USD. Eq (40) for option P&L of the n -th roll is modified as follows

$$OptionP\&L^{USD}(t; t_0^n, T^n) = \sum_{k'} N_{k'}(t_0^n) (S_t V_{k'}^{BTC}(t, T^n) - S_{t_0^n} V_{k'}^{BTC}(t_0^n, T^n)), \quad (47)$$

where the value of option premiums at the call inceptions is swapped using the spot rate of $S_{t_0^n}$ and the current value is wrapped using the prevalent rate S_t .

Using Eq (27) for conversion of BTC P&L into USD P&L along with Eq (41) for delta-hedge P&L is changed as

$$\begin{aligned} DeltaP\&L^{USD}(t; t_0^n, T^n) &= \sum_{t_h} S_{t_h} \frac{F_{t_h} - F_{t_{h-1}}}{F_{t_h}} \Delta_{perp}^{BTC}(t_{h-1}, T^n) \\ &\quad - \eta \sum_{t_h} S_{t_h} |\Delta_{perp}^{BTC}(t_h, T^n) - \Delta_{perp}^{BTC}(t_{h-1}, T^n)| \\ &\quad + DeltaFunding^{USD}(t; t_0, T). \end{aligned} \quad (48)$$

Term $DeltaFunding^{USD}(t; t_0^n, T^n)$ is the delta funding costs in USD defined in Eq (31).

The total USD P&L of the n -th roll is computed by

$$TotalP\&L^{USD}(t; t_0^n, T^n) = OptionP\&L^{USD}(t; t_0^n, T^n) + DeltaP\&L^{USD}(t; t_0^n, T^n). \quad (49)$$

Cumulative USD P&Ls from option premiums and delta-hedging realised during time period (t_s, t) with n rolls are given by

$$\begin{aligned} CumTotalOptionP\&L^{USD}(t) &= \sum_{n'=1..n-1} OptionP\&L^{USD}(T^{n'}; t_0^{n'}, T^{n'}) + OptionP\&L^{USD}(t; t_0^n, T^n) \\ CumTotalDeltaP\&L^{USD}(t) &= \sum_{n'=1..n-1} DeltaP\&L^{USD}(T^{n'}; t_0^n, T^n) + DeltaP\&L^{USD}(t; t_0^n, T^n). \end{aligned} \quad (50)$$

The cumulative total USD P&L of the strategy realised over n rolls is given by

$$CumTotalP\&L^{USD}(t) = CumTotalOptionP\&L^{USD}(t) + CumTotalDeltaP\&L^{USD}(t). \quad (51)$$

We show the decomposition of USD P&L explain of in Subplot (B1) of Figure (5).

The account value in USD at time t is computed as the sum

$$\Pi^{USD}(t) = D_0^{USD} + CumTotalP\&L^{USD}(t), \quad (52)$$

where we ignore the USD funding rates. The account value in BTC is computed using prevalent spot rate S_t :

$$\Pi^{BTC}(t) = \frac{1}{S_0} D_0^{USD} + \frac{1}{S_t} CumTotalP\&L^{USD}(t), \quad (53)$$

where we exclude the performance of the initial deposit in BTC using fixed swap rate S_0 observed at strategy inception.

5.2 Illustrative strategies

To implement historical simulation of option strategies using Deribit data, we make the following assumption regarding costs of delta and option trading, and the delta-hedge execution for our backtest simulations.

Assumption 5.1 (Transaction Costs). *Transaction cost for delta-hedging using perpetual futures is proportional to traded Coin or USD amount with multiple η set to 5bp, $\eta = 0.0005$ (see Eq (41)).*

Transaction cost for buying and selling an option contract is proportional to traded premium with charge c ratio set to 50bp, $c = 0.005$. The traded premium is computed as the mid of the bid and ask prices.

In our opinion, these costs are representative of actual trading costs on Deribit exchange.

Assumption 5.2 (Delta-hedge execution). *Given time series of option prices and deltas, the portfolio delta is computed using Eq (29) every hour and the delta hedge is implemented using the last price of the perpetual futures.*

In practical applications portfolios delta would be typically rebalanced within bands, to reduce delta-hedging costs. Optimised hedging produces better risk-adjusted results, but it is subject to trader's risk tolerance. Thus, we do not apply any optimisation in this paper and follow the simple time-based re-balancing for brevity.

5.2.1 Call Overwrite Strategy

We start with a simple call overwrite strategy which is very popular in DeFi. When using this strategy, an investor deposits an amount of Π_0^{BTC} coins which is used as a collateral for selling at-the-money call options on the same coin. P&L from traded options is settled against the remaining collateral. The strategy regularly rolls a short position in at-the-money call options with sizes equal to the present amount of BTC collateral. Naturally this strategy is implemented using Coin-based accounting.

In Figure (2) we show the performance of the call overwrite strategy that sells at-the-money BTC calls with the maturity of one week with weekly rolls on every Friday. The initial deposit is 1 BTC. As a benchmark, we use long only strategy with holds 1 BTC.

In subplot (A1) we show the coin performance of the strategy using Eq (34). When BTC rallies, realized roll P&L is negative so that the amount of BTC held in the strategy drops. In subplot (A2) we show the scatter plot of the daily coin performance vs the daily BTC return. It clear that the strategy is short call so its beta coin exposure is negative.

In subplot (B1) we show USD performance computed using Eq (35). For the long only strategy the performance corresponds to the price path of BTC-USD rate S_t . The call overwrite strategy in USD partially benefits from BTC appreciation over time because the margin is held in BTC. In subplot (B2), we show the scatter plot of daily returns for USD performance. Now, because of the BTC margin, the strategy in USD has a positive beta to BTC return.

The performance of the call overwrite strategy in BTC is slightly negative, which indicates that selling call options without delta-hedging may not be profitable way to harvest the short volatility risk-premia. In comparison with long-only strategy in USD, the call overwrite strategy produces a smaller total return. However the strategy delivers better risk-adjusted return because the short call reduces the long-only portfolio volatility.

As a result, we view the call over-write strategy as a risk-mitigation strategy which reduces the portfolio volatility.

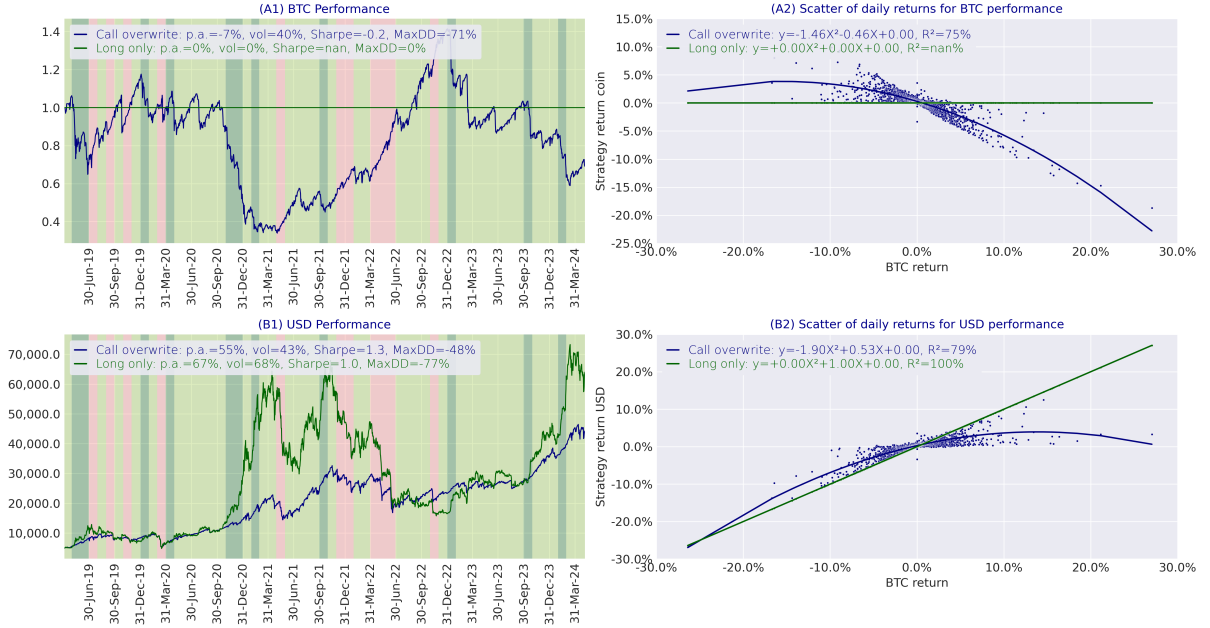

Figure 2: Performances of BTC call option overwrite strategy using Coin accounting and long only strategy holding 1BTC. The simulation time period is from 30Mar2019 to 5Oct2023. Notation in legends of subplots (A1) and (B1): p.a. is annualised return or CAGR, vol is annualised volatility of daily log returns, Sharpe is Sharpe ratio computed using zero risk-free rate, MaxDD is maximum drawdown; background colors are the same as in Figure (1). Notation in legends of subplots (A2) and (B2): the equation is estimated using the quadratic regression with weekly log-returns of the strategy predicted by BTC-USD weekly return, R^2 is the adjusted R-squared of the estimated quadratic regression.

5.2.2 Put selling strategy

Put selling strategy is another popular strategy second to call overwrite strategy. When using this strategy, an investor deposits an amount of Π_0^{BTC} coins which is used as collateral for selling at-the-money put options. We note that put selling account must be a margin account because a short position in inverse put option must be liquidated if the spot drops more than 50% of the strike price (in this case, the price of the put will be worth more than one coin which exceeds the initial margin). Realised option P&L is settled against the collateral. The size of each new roll is equal to the present amount of coin Π_t^{BTC} .

In Figure (3), we show the performance of the put selling strategy that sells at-the-money BTC puts with the maturity of one week with weekly rolls on every Friday. The initial deposit is 1 BTC. As a benchmark, we use long-only strategy holding 1 BTC. Subplot (A1) illustrates the coin performance of the strategy using Eq (34). When BTC crashes, the outstanding margin drops. Subplot (A2) illustrates the scatter plot of the weekly coin performance vs weekly BTC return. The strategy is short put so its beta coin exposure is positive. In subplots (B1) and (B2) we show USD performance computed using Eq (35) and the scatter plot of daily returns for USD performance, respectively. The performance of the long only strategy corresponds to the price path of BTC-USD rate S_t .

The performance of the put selling is slightly negative, which indicates that selling put options without delta-hedging may not be profitable, similarly to selling call options. In comparison with long-only strategy in USD, the short put strategy is leveraged to BTC

performance because of long delta from the short put exposure and long delta from the deposit. Thus, we view the put selling strategy as a leveraged long exposure to BTC performance.

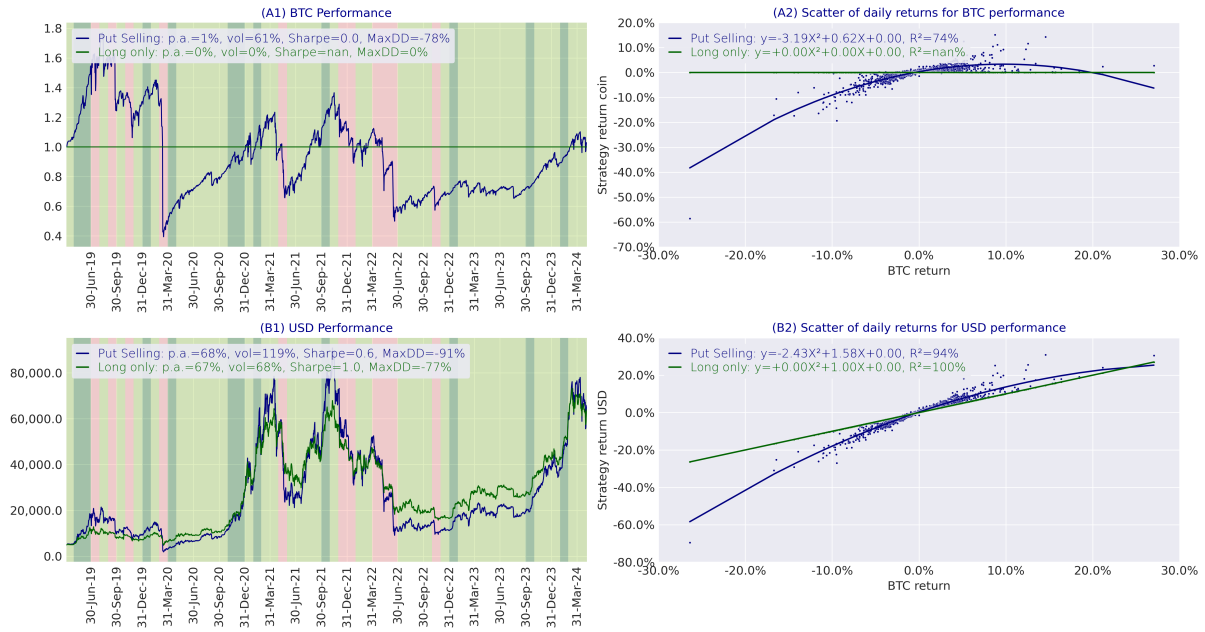

Figure 3: Performances of BTC put selling strategy and BTC long only strategy. Notations are the same as in Figure (2).

5.2.3 Delta-hedged short straddle strategy

We now consider a delta-hedged option strategy which systematically sells at-the-money call and put options through regular rolls. Options are held to maturity and the portfolio is delta hedged. We simulate weekly rolls with delta hedge executed hourly.

Coin accounting

We take the initial deposit of 1 BTC, for each roll the number of sold calls and puts equals to the account value right prior to the roll time: $N(t_0^n) = \Pi^{BTC}(t_0^n)$.

In Figure (4) we show the performance of the short straddle strategy. In subplot (A1) we show the performance of the cumulative P&L of the total, option, and delta parts using Eq (43). We see that the cumulative option P&L standalone may become negative so that its volatility and Sharpe ratio cannot be computed. Delta-hedge P&L is negatively correlated with options P&L, so that the delta-hedge strategy has smaller volatility and higher risk-adjusted performance. In the long-term both option and delta-hedge P&L are profitable. In contract to selling ATM puts and calls without hedging, which sell fewer sizes after a drawdown, the delta-hedging mitigates drawdowns of the delta-hedged strategy so that the delta-hedged strategy sells bigger option sizes through market cycles.

In subplot (B1), we show the USD performance of the strategy computed using Eq (46). The coin account keeps realised profits in BTC so over time it increases the exposure to BTC and the volatility of the strategy increases in USD terms. In subplots (A2) and (B2), we illustrate the scatter plot of strategy weekly returns in BTC and USD, respectively, versus BTC-USD returns. We see that the strategy is close to be delta-neutral for coin accounting, with its returns profile being short convexity. For USD performance, the strategy NAV increases exposure to BTC through accrued profits so that it produces a positive beta to BTC.

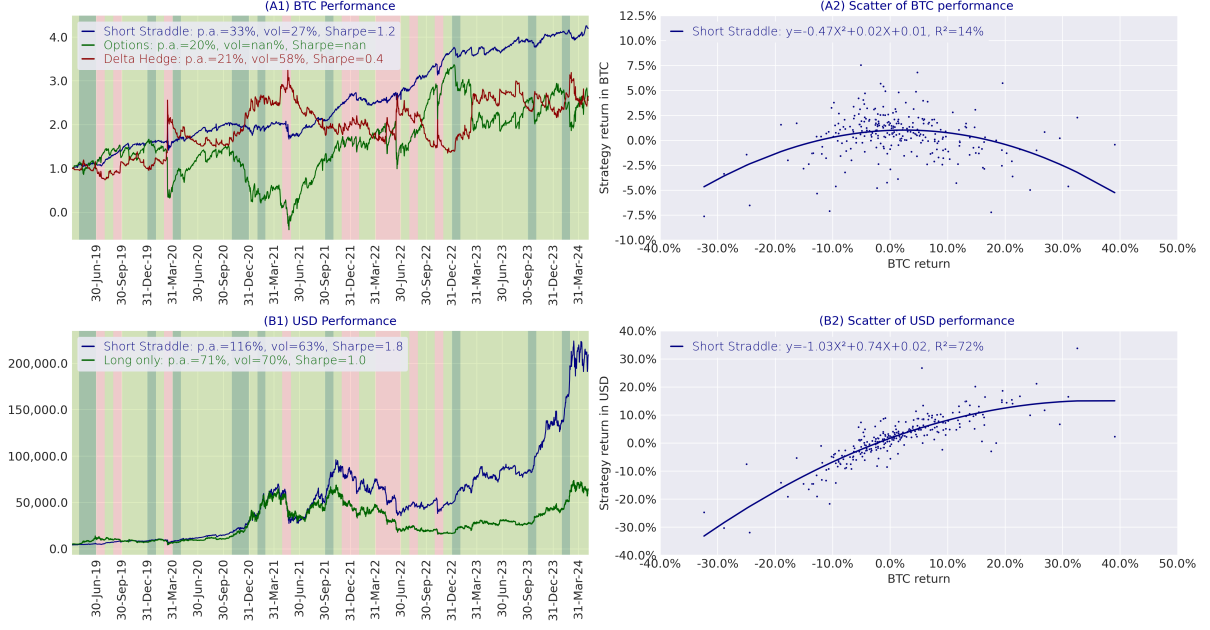

Figure 4: Performance of BTC delta-hedged straddle strategy using Coin accounting. Notations are the same as in Figure (2).

USD accounting

For USD accounting, the set the initial USD deposit equal to the price of 1BTC, $D_0 = S_0$. Strategy Coin P&L is swapped into USD P&L at the prevailing spot rate. In Figure (5), we show the performance of the same strategy as in Figure (4). The number of contracts traded $N(t_0^n)$ is set to the BTC value of the account $\Pi^{USD}(t)/S_t$.

In Subplot (A1) we show the USD P&L using Eq (50). We see that, when measured in BTC, the strategy with USD accounting indicates a poorer risk-adjusted performance. The risk-adjusted USD performance of the strategy using USD accounting is similar to the risk-adjusted Coin performance of the same strategy using Coin accounting. In Subplots (B1) and (B2) we show BTC and USD performance using Eq (53), respectively. In BTC terms the strategy is short BTC. In USD terms the strategy is delta-neutral with a classic profile of short convexity.

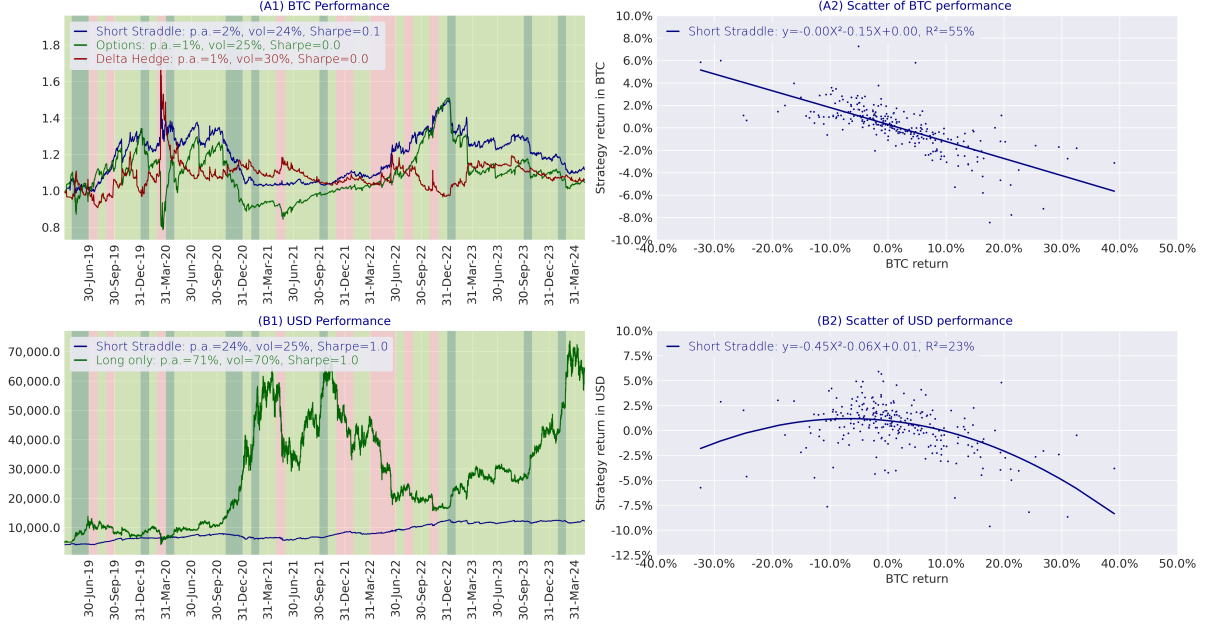

Figure 5: Performance of BTC delta-hedged straddle strategy using USD accounting. Notations are the same as in Figure (2).

5.2.4 Discussion

We conclude with important conclusion regarding Coin-based and USD-based accounting. Strategies with BTC accounting are suitable for investors who would like to have exposure to BTC (through accrued options and delta-hedge P&L). The performance of delta-hedged strategies is BTC-neutral, but their USD performance is not due to the exposure of realised coin P&L.

Strategies with USD-based accounting is suitable for investors who would like to keep a neutral exposure to BTC. These are strategies with delta-hedging and with USD funding by necessity to remove BTC exposure. Delta-hedged USD performances of these strategies are BTC-neutral by construction. However, if BTC out-performances over longer time period, BTC values of realised P&L of these strategies will decline.

Importantly, for a given strategy, the risk-adjusted performance in Coin terms when using Coin accounting is about the same as the risk-adjusted performance in USD terms when using USD accounting. Slight differences may arise from portfolio compounding and trade sizing effects.

5.3 Backtest of systematic delta-hedged strategies

We examine the risk-premia in crypto options traded on Deribit exchange by simulating delta-hedged strategies using Deribit options data. We consider single leg strategies and multi-leg option strategies. For each strategy, we implement the long and short positions. We implement weekly (Friday every week), monthly (last Friday of a month), and quarterly rolls (last Friday of a quarter). At each roll at 8 : 00 UTC the existing option position is closed and new position with options expiring on next Friday is opened. For each roll, the number of contracts, or the size, traded is proportional to the current Coin NAV: $N(t) = \Pi^{BTC}(t)$. We note that because the sizing is a path-dependent function of the realized P&L, the performances of long and short positions are not symmetric. We follow the auto-compounding because its most used in practice.

For computing performance of different strategies we use Deribit options data from 30Mar2019 to 5Oct2023. We apply assumptions (5.1) and (5.2) in our backtest simulations. When choosing strikes corresponding to given option deltas on the grid, we select the adjacent strike with maximum open interest.

5.3.1 Single leg strategies

Single leg strategies include options with following strikes (NB: we need to decide whether we use Deribit or Blacks delta):

- ATM: calls and puts with at-the-money strikes;
- 25D: options with strikes corresponding to delta of +0.25 for calls and -0.25 for puts;
- 10D: options with strikes corresponding to delta of +0.10 for calls and -0.10 for puts.

In Tables (1) and (2), we show risk-adjusted Coin and USD performances of strategies using Coin-based and USD-based accounting, respectively. We see that, for each strategy, the risk-adjusted Coin performance under Coin-based accounting is close to the risk-adjusted USD performance under USD-based accounting.

It is evident that the risk-premium in Bitcoin options is negative because long option positions are not profitable over a long time period, while short option positions are profitable. Realised Sharpe ratios for shorting ATM, 25D, 10D calls is higher than those for shorting corresponding puts, which indicates extra negative risk-premiums for crypto calls. These risk-premiums for crypto call may arise from leverage-seeking preferences of crypto investors for obtaining upside potential. We also see that overall BTC options have higher negative risk-premiums compared to ETH options.

Table 2: Risk-adjusted USD performances of delta-hedged single leg option strategies on BTC and ETH using USD-based accounting for option maturities of one week. Notations are the same as in Table (1).

In Figure (6), we report the regime conditional performances of single leg strategies with weekly rolls using Coin-based accounting. The BTC and ETH regimes for the performance period are obtained by ordering the monthly returns from lowest to highest and the splitting the 16% of worst returns into "bear" regimes, 16% of best returns into "bull" regimes, and remaining regimes into "normal" regimes. The logic behind using these quantiles is that, under normal distribution, "bear"/"normal"/"bull" regimes represent returns below/within/above one standard deviation. Using regime conditional performances, we compute the average performance multiplied by regime frequencies divided by the total volatility, so that we obtain the decomposition of the total Sharpe ratio by regimes.

The most interesting observation is that long ATM call on average is unprofitable in all regimes including the bull regime. The reason is that during bull periods implied call volatilities increase, so long positions rolls into options with higher implied volatilities than subsequent volatilities realised through delta-hedging. For ETH options, performances of long 25D and 10D puts are slightly positive in bear regimes. All short positions are most profitable in the normal regime (68% frequency).

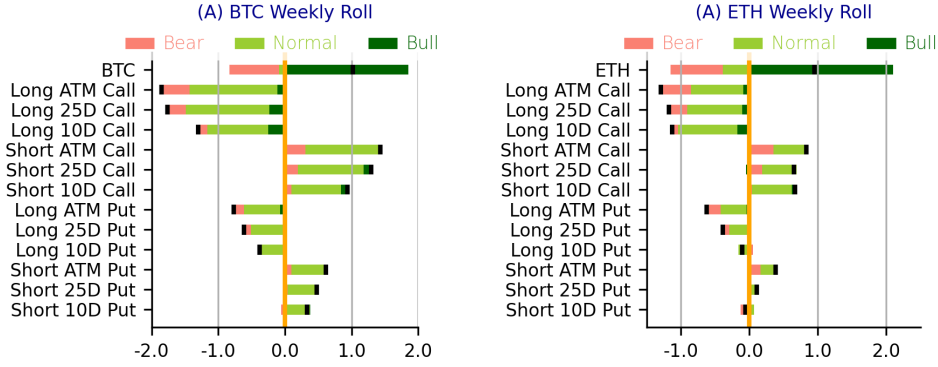

Figure 6: Regime conditional Sharpe ratios of delta-hedged single leg option strategies on BTC (left) and ETH (right) using Coin accounting for maturity of one week. The black bar is the total Sharpe of the strategy.

5.3.2 Multi-leg Strategies

Single leg options are either short or long delta, theta, and gamma. Multi-leg strategies allow to create greek-neutral positions so isolate harvesting of the risk-premia in overall volatility or in call or put spreads.

We consider the following multi-leg strategies include the following strategies.

- ATM straddle consists of equal size position in call and put options with at-the-money (ATM) strikes;
- 25D strangle consists of equal size position in call and put options with delta of $+0.25$ and -0.25 , respectively;
- 10D strangle consists of equal size position in call and put options with delta of $+0.25$ and -0.25 , respectively;
- 25D call spread consists of shorting one unit of call with delta of $+0.50$ and of being long two units of call with $+0.25$ delta;

- 25D put spread consists of shorting one unit of put with -0.50 delta and being long two units of put with delta of -0.25 ;
- 25D risk reversal consists of shorting one unit of put with -0.25 delta and being long one unit of call with delta of 0.25 ;
- 25D butterfly ratio consists of long $+0.50$ and -0.50 delta call and put and short -0.25 and -0.25 delta for call and put.

ATM straddle, 25D and 10D strangles are about delta-neutral at the inception, they are either long or short gamma, and they produce direct exposure to the volatility risk-premia. Call and put spreads are close to delta-neutral and they produce exposure to the risk-premia of call skew and put skew, respectively, relative to the ATM volatilities. The long position in the call spread is expected to be profitable if out-of-the-money (OTM) call volatilities are cheaper than at-the-money volatilities. Symmetrically, the long position in the bear spread is expected to be profitable if out-of-the-money put volatilities are cheaper than at-the-money volatilities. The risk reversal is close to being gamma neutral and it is profitable if OTM call volatilities are cheaper than OTM put volatilities. The butterfly is close to delta-neutral with negative theta at the inception and it provides the exposure to the risk-premia of the implied convexity (tails of returns distribution). For each strategy, we simulate both the long and short implementation.

For brevity, we skip results of strategies using USD-based accounting because USD risk-adjusted performances are close to Coin risk-adjusted performances of strategies under Coin-based accounting. Thus, we report the risk-adjusted coin performances using Coin-based accounting. To examine if the risk-premia depends on time-to-expiry, we simulate strategies using three rolls: weekly (Friday every week), monthly (last Friday of the month), quarterly (last Friday of the quarter). At every roll event, the strategy trades in options expiring at the roll maturity and holds them to the maturity. Delta hedging is implemented on hourly basis.

In Tables (3), (4), (5), we show the risk-adjusted coin performances with weekly, monthly, and quarterly rolls, respectively. We see that the performance of all long strategies is negative. This indicates that the risk-premia in crypto options is negative for the level, the put and call skew, and the (tail) convexity. We observe that the most profitable strategies are short straddles, strangles and butterflies, which indicates that implied volatilities are higher than the realised volatilities on average. We see that the risk-premia is most negative for short-dated options.

For weekly rolls, call and put spread strategies with exposures to 25D call and 25D put volatilities relative to ATM volatilities are not profitable either on short or on long side after transaction costs. For monthly and quarterly rolls, short call spread is profitable, indicating that call volatilities for longer-dated options may be overvalued relative to put volatilities.

Risk-adjusted performances for short strategies with quarterly rolls are the poorest for BTC, and negative for ETH. For strategies on ETH with quarterly rolls the risk-adjusted performances of both long and short strategies are insignificant, so without accounting for trading costs the risk-premia may be zero.

We see that strategies with quarterly rolls have higher volatilities and betas to the performance of the underlying cryptocurrency because longer-dated options have higher vega exposures. We conclude that long strategies produce negative betas to the underlying performance because implied volatilities tend to increase when the underlying drops. As

a the delta-hedged long strategies benefit from long vega exposure when the underlying drops.

Table 5: Risk-adjusted performances of delta-hedged multi-leg option strategies on BTC and ETH using Coin accounting for quarterly rolls. Notations are the same as in Table (1).

In FinalFigures (7) and (8), we show the regime conditional performances of simulated strategies on BTC and ETH underlyings for the three frequencies of the roll. It is remarkable that long volatility strategies with weekly rolls generate negative performances in all regimes. Long straddle strategies with monthly and quarterly rolls generate positive performance in bear regime. Long strangles with quarterly rolls generate positive performance in bear regimes too. Short volatility strategies with weekly rolls generate positive performance in all regime. The reason is that any short-term losses cause with higher price volatility of the underlying coin tend to be compensated by higher risk-premiums for new option rolls.

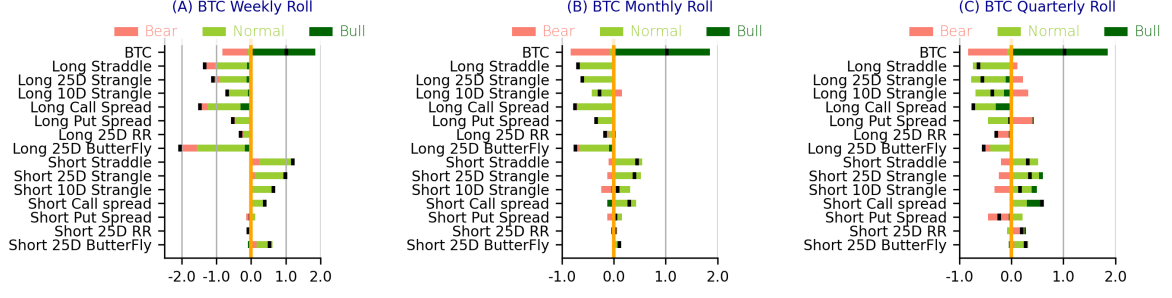

Figure 7: Regime conditional Sharpe ratios of delta-hedged multi leg option strategies on BTC with weekly (left), monthly (middle), and quarterly (right) rolls. Regimes are defined in the same as for figure (6).

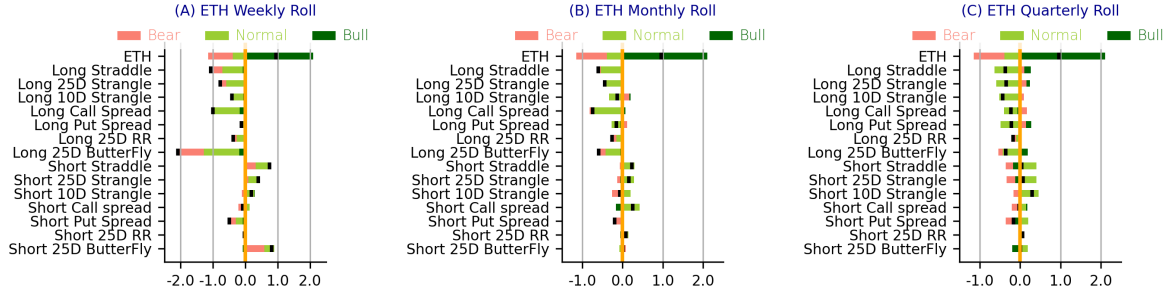

Figure 8: Regime conditional Sharpe ratios of delta-hedged multi leg option strategies on ETH with weekly (left), monthly (middle), and quarterly (right) rolls. Regimes are defined in the same as for figure (6).

6 Conclusions

We consider valuation and delta-hedging of inverse options. We apply the uniqueness of fair price under different martingale measures and the numéraire invariance principle to derive formulas (9) and (12) for valuation and hedging of inverse options, respectively.

We introduce USD- and Coin-based accounting rules for measurement of realised performances of delta-hedged strategies in inverse options. We simulate a number of popular option strategies on Bitcoin and Ether underlyings using data from Deribit exchange for past four years. We show that the risk-adjusted performance in coin terms of the account with Coin-based accounting is close to the risk-adjusted performance in USD terms of the account with USD-based accounting. This result validates empirically the numéraire invariance principle discussed in Section A. An investor, who would like to have a long-term exposure to underlying coin, should opt for Coin-based accounting, under which the strategy accrues the coin P&L (which is native to Deribit exchange). In opposite an investor, who would like to keep neutral exposure to coin performance, should choose the USD-based accounting, under which realised coin P&L is immediately swapped into USD.

We conclude that the risk-premia observed in crypto options is negative for both level, put and call skew, and convexity. Delta-hedging is necessary for harvesting the risk-premia because simple call overlay or put selling strategies bear directional market risk. Short strategies with frequent rolls (such as weekly) appear to be best suited for harvesting the volatility risk-premia. Defensive long volatility strategies should be trading in options

with longer maturities. This conclusion is also observed in traditional options markets on equity indices¹⁰.

A A note on the Numéraire invariance

The numéraire invariance is a fundamental economic fact stating that a self-financing portfolio remains self-financing after the tradeable asset in whose units the portfolio holdings are expressed (most typically cash) is changed to another tradeable asset in the economy. Despite being very intuitive (in some sense obvious), the standard textbook treatment of establishing the numéraire invariance entails a full proof relying on manipulations using the Itô formula and properties of quadratic variation. We provide an alternative derivation which, in our mind, much more closely lines up with the underlying intuition,

We denote the price vector of tradeable assets by A_t and consider a trading strategy holding θ_t units of assets A_t . We assume that A_t is adapted to the underlying filtration $\{\mathcal{F}_t\}$, and recall that the strategy is called self-financing if for the resulting portfolio $V_T \equiv \theta_T \cdot A_T$ we have

$$V_T = \int_0^T \theta_t \cdot dA_t. \quad (54)$$

We assume that the paths of A_t and the portfolio holdings θ_t are corlol semimartingales, and that all the information in the underlying economy is encapsulated by the process A_t , that is, we assume that (modulo the null sets) $\{\mathcal{F}_t\}$ is generated by A_t . By the pathwise representation of the stochastic integral (e.g. [Sondermann \[2006\]](#), [Karandikar \[1995\]](#))

$$\int_0^T \theta_t \cdot dA_t = \phi_T(\theta, A), \quad T \geq 0,$$

where for every $T > 0$, $\phi_T(\cdot, \cdot)$ is a measurable functional of the corlol paths. We put $\varphi_T(\cdot) \equiv \phi_T(\theta, \cdot)$, and from (54) conclude that $\varphi_T(x) = \theta_T \cdot x_T$ holds $\mathbb{Q}_A$ a.s., where $\mathbb{Q}_A$ is the probability measure induced on the set of corlol paths by A_t . Setting $x_t \equiv \frac{A_t}{M_t}$ for some strictly positive tradeable asset M_t yields

$$\theta_T \cdot \frac{A_T}{M_T} = \int_0^T \theta_t \cdot d\left(\frac{A_t}{M_t}\right),$$

establishing the numéraire invariance.
